## Abstract

In many legumes, root entry of symbiotic nitrogen-fixing rhizobia occurs *via* host-constructed tubular tip-growing structures known as infection threads. Here we have used a confocal microscopy live-tissue imaging approach to investigate early stages of infection thread formation in *Medicago truncatula* root hairs expressing fluorescent protein fusion reporters. This has revealed that infection threads only initiate 10-20 h after the completion of root hair curling, by which time major modifications have occurred within the so-called infection chamber, the site of bacterial entrapment. These include the accumulation of exocytosis (MtVAMP721e) and cell wall (MtENOD11)-associated markers, concomitant with radial expansion of the chamber. Significantly, the infection-defective *Mtnin-1* mutant is unable to create a functional infection chamber. This underlines the importance of the *NIN*-dependent phase of remodeling of the host cell wall that accompanies bacterial proliferation and precedes infection thread formation and leads us to propose a novel two-step model for *Rhizobium* infection initiation in legume root hairs.

## 1 Introduction

2 Legumes possess the remarkable capacity to improve their nutrition by establishing a  
3 nitrogen-fixing root nodule symbiosis (RNS) with soil bacteria collectively called rhizobia. In  
4 many legumes such as *M. truncatula*, rhizobia penetrate across the root epidermis and outer  
5 cortex to reach the differentiating nodule tissues *via* sequentially constructed transcellular  
6 compartments known as infection threads (ITs; Gage, 2004). It is now well established that  
7 this mode of entry through specialized infection compartments, often referred to as  
8 accommodation, is shared with the more ancient arbuscular mycorrhizal (AM) symbiosis from  
9 which the legume-*Rhizobium* RNS is thought to have evolved (Parniske, 2008; Markmann  
10 and Parniske, 2009). Furthermore, strong evidence indicates that the signaling and cellular  
11 mechanisms underlying IT formation in legumes are closely related to those used for  
12 infection compartment formation during AM infection of epidermal and outer cortical tissues  
13 (Bapaume and Reinhardt, 2012; Oldroyd, 2013).

14 Rhizobial infection is set in motion after an initial molecular dialogue between symbiotic  
15 partners, in which rhizobial lipochito-oligosaccharide Nod factors (NFs) are key signaling  
16 molecules (reviewed in Oldroyd, 2013). Host responses to NF signaling include rapid and  
17 sustained nuclear-associated  $\text{Ca}^{2+}$  oscillations ( $\text{Ca}^{2+}$  spiking) (Ehrhardt et al., 1996; Oldroyd  
18 and Downie, 2006; Sieberer et al., 2009; Capoen et al., 2011) and the rapid expression of  
19 early epidermal marker genes such as *M. truncatula ENOD11* (Charron et al., 2004). The  
20 activation of nuclear  $\text{Ca}^{2+}$  spiking is one of the most characteristic features of the so-called  
21 SYM signaling pathway, common to both RNS and AM (Kistner and Parniske, 2002; Singh  
22 and Parniske, 2012). Whilst these pre-infection responses to NFs are observed in the  
23 majority of elongating root hairs (RHs) early after rhizobial inoculation (Journet et al., 2001;  
24 Wais et al., 2002), ITs are only formed in a small sub-set of RHs, and *MtENOD11* expression  
25 is strongly activated at these rhizobial infection sites (Journet et al., 2001; Boisson-Dernier et  
26 al., 2005).

27 ITs are tubular plant-derived structures delimited by a membrane which is contiguous with  
28 the RH plasmalemma and a layer of cell wall-like material, thus isolating the rhizobia from the  
29 host cell cytoplasm (Gage, 2004). These apoplastic infection compartments are  
30 progressively constructed along the length of the RH with their growing tip connected *via* a  
31 cytoplasmic bridge to the migrating RH nucleus. This broad cytoplasmic column provides the  
32 cell machinery for tip growth which involves targeted exocytosis of membrane and  
33 extracellular materials to the growing apex of the IT (Oldroyd et al., 2011; Bapaume and  
34 Reinhardt, 2012). It is presumed that this cytoplasmic bridge shares an equivalent role to the  
35 pre-penetration apparatus (PPA) formed at the onset of AM fungal infection (Genre et al.,  
36 2005; Genre et al., 2008). We now know that the IT tip region is formed in advance of  
37 rhizobial colonization and is progressively populated by dividing rhizobia which also

1 physically move down the thread (Gage, 2004; Fournier et al., 2008). It has been proposed  
2 that the matrix of the growing IT tip is initially in a fluid or gel-like state compatible with  
3 bacterial growth and movement (Brewin, 2004; Fournier et al., 2008). This relative plasticity  
4 could result in part from the presence of atypical extracellular (glyco)-proteins such as the  
5 repetitive Pro-rich proteins MtENOD11/12 because their low Tyr content is presumed to limit  
6 cross-linking to other wall components (Scheres et al., 1990; Pichon et al., 1992; Journet et  
7 al., 2001).

8 Nevertheless, the mechanism by which rhizobial IT formation is initiated in RHs is not clear.  
9 Whereas AM fungal hyphae form contact structures called hyphopodia on the exposed  
10 surface of non-hair epidermal cells prior to PPA formation and peri-fungal infection  
11 compartment formation (Genre et al., 2005), rhizobial entry requires that the bacteria first  
12 become entrapped between RH walls. Attachment of rhizobia close to a growing RH tip  
13 induces a continuous reorientation of tip growth, most likely the result of localized NF  
14 production (Esseling et al., 2003), eventually leading to RH curling and subsequent bacterial  
15 entrapment within a closed chamber in the centre of the curl (Catoira et al., 2001; Geurts et  
16 al., 2005). Rhizobial entrapment can also occur between the cell walls of two touching RHs  
17 (Dart, 1974; Gage, 2004).

18 The closed chamber in curled RHs has often been termed the infection pocket (e.g. Murray,  
19 2011; Guan et al., 2013). However, because this term is also used to designate a quite  
20 different and larger structure formed in root sub-epidermal tissues of legumes during  
21 intercellular infection following “crack entry” and involving localized cell death (Goormachtig  
22 et al., 2004), we propose to use the term “infection chamber” to describe the unique  
23 enclosure formed during rhizobial RH infection.

24 Following entrapment, it has been proposed that rhizobia multiply to form a so-called  
25 ‘microcolony’ (Gage et al., 1996; Limpens et al., 2003) and that IT polar growth initiates in  
26 front of this microcolony by local invagination of the RH plasmalemma combined with  
27 exocytosis of extracellular materials (Gage, 2004). Furthermore, it has been suggested that  
28 localized degradation of the chamber wall would allow the rhizobia to access the newly  
29 formed IT (Callaham and Torrey, 1981; Turgeon and Bauer, 1985). However a detailed  
30 investigation of this particular stage of rhizobial infection is missing and in particular when  
31 and where the rhizobia/cell wall interface becomes modified. Such studies have been limited  
32 until now, notably because ITs develop only in a low proportion of curled RHs (Dart, 1974).

33 To attempt to answer this question we have used a live tissue imaging approach developed  
34 for in vivo confocal microscopy in *M. truncatula* (Fournier et al., 2008; Cerri et al., 2012;  
35 Sieberer et al., 2012), and particularly well adapted to time-lapse studies of the initial stages  
36 of rhizobial infection including RH curling and IT formation. To investigate modifications  
37 occurring at the RH interface with the enclosed rhizobia during these early stages, we

prepared *M. truncatula* plants expressing fluorescent protein fusions aimed to detect both exocytosis activity and cell wall remodeling during the initial construction of the IT apoplastic compartment. To this end we made use of the *M. truncatula* Vesicle-Associated Membrane Protein721e (MtVAMP721e; Ivanov et al., 2012) recently shown to label exocytosis sites in both growing RHs and during AM colonization (Genre et al., 2012) as well as the infection and cell-wall associated MtENOD11 Pro-rich glycoprotein (Journet et al., 2001). Our experiments have revealed that IT development in curled RHs only initiates after a lengthy interval of 10-20 h during which sustained exocytosis and MtENOD11 secretion to the infection chamber is associated with radial expansion as well as remodeling of the surrounding walls. Importantly, it was found that the infection-defective *Mtnin-1* mutant (Marsh et al., 2007) is impaired in chamber remodeling. Our findings lead us to propose a new model for IT formation in which the infection chamber first differentiates into a globular apoplastic compartment displaying similarities to the future IT and in which the enclosed rhizobia multiply. This is then followed by a switch from radial to tubular growth corresponding to tip-driven IT growth and associated movement of rhizobia into the extending thread. Importantly, this two-step model no longer requires that the host cell wall is degraded in order to allow access of the colonizing rhizobia to the newly initiated IT.

## Results

### ***Infection thread tip-growth in M. truncatula initiates 10-20 hours after the completion of root hair curling***

In order to study the cellular events associated with IT initiation, a live-tissue imaging approach was used to identify and continuously monitor RHs at different stages of curling and rhizobial entrapment (Fournier et al., 2008; Cerri et al., 2012). The observation of many such RHs surprisingly revealed that IT tip growth only initiated many hours following the completion of curling and in no case did we observe IT formation immediately after curling. In the example shown in Fig. 1, RH curling around the entrapped rhizobia is close to completion at the initial time point of observation (Fig. 1A). The unchanged position of the RH tip in Fig. 1B-C (single arrowhead) indicates that curling had terminated during the first 1.5 h period. Tubular IT formation was not observed during the following 7.5 h despite the fact that the nucleus and associated cytoplasm are stably localized in the curled tip region of the RH (Fig. 1B-D). However, a growing IT was observed within this particular RH 15 h later (Fig. 1E) and continued its progression during the following hours (not shown). Based on the length of the IT in Fig. 1E, we estimate that elongation had been underway for approximately 6-8 h (average growth rate of ITs is 4-5  $\mu\text{m.h}^{-1}$  in *M. truncatula*; Fournier et al., 2008). Thus, in this particular case, the delay between the completion of RH curling and IT initiation can be

1 estimated to be around 15-18 h. Similar image series obtained for a number of other RHs  
2 initiating infection have together revealed that the delay between the completion of bacterial  
3 entrapment and IT initiation is in the range of 10-20 h. During this lengthy period the infection  
4 chamber became progressively easier to distinguish from the surrounding cytoplasm, most  
5 likely as a consequence of enlargement and surface modifications prior to IT initiation (Suppl.  
6 Fig. S1). To further investigate this, we have exploited fluorescent cellular markers for  
7 monitoring both host exocytosis activity and possible modifications to the infection chamber  
8 extracellular matrix.

### 9 10 ***The GFP-MtVAMP721e exocytosis marker accumulates rapidly around the newly*** 11 ***formed infection chamber***

12 To evaluate potential exocytosis activity associated with the RH infection chamber we made  
13 use of *M. truncatula* plants expressing a fluorescence-tagged MtVAMP721e (Genre et al.,  
14 2012; Ivanov et al., 2012) in their roots. In non-inoculated or non-colonized RHs, the GFP-  
15 MtVAMP721e fusion protein primarily localizes to the vesicle-rich region behind the growing  
16 tip of elongating RHs and at lower levels as localized puncta elsewhere in the cytoplasm  
17 (Genre et al., 2012, and Fig. 2A). Our *in vivo* observations have revealed that the GFP-  
18 VAMP721e fluorescent signal is no longer located to the RH tip region of fully curled RHs  
19 with entrapped rhizobia, but now surrounds the infection chamber, outlining its contours (Fig.  
20 2A). This signal is presumably associated with the plasma membrane bordering the infection  
21 chamber, most likely corresponding to the accumulation of GFP-VAMP-labeled vesicles. By  
22 monitoring such curled RHs over time, we further discovered that the exocytosis reporter is  
23 continuously present around the infection chamber (e.g. over the entire 7 h period illustrated  
24 in Fig.2A-C). This suggests a lengthy period of sustained exocytosis targeted towards the  
25 infection chamber. This continuous exocytosis activity was directly associated with radial  
26 expansion of the infection chamber at the same period of time. Our results thus argue that  
27 membrane and extracellular material are actively conveyed towards the infection chamber  
28 following the completion of RH curling and prior to IT initiation. As illustrated in Fig. 2D-F, the  
29 continuous enlargement of the infection chamber is accompanied by progressive  
30 multiplication of the enclosed rhizobia.

31 In order to investigate in more detail when host membrane/cell wall interface remodeling is  
32 initiated following RH curling, we focused on the earliest stages of infection chamber  
33 formation. Tip-focused accumulation of GFP-MtVAMP721e characteristic of elongating RHs  
34 (Genre et al., 2012, and Fig. 2A) persists during RH curling around attached rhizobia (Fig.  
35 2G and I). However, as soon as RH tip curling is completed fluorescence labeling at the RH  
36 tip is lost (Fig. 2H, dashed arrow). Importantly, Figure 2J shows that the accumulation of

1 GFP-MtVAMP721e around enclosed rhizobia initiates within the first hours following the  
2 completion of RH tip curling. Taking into account the fact that rhizobial cell division within  
3 growing *Medicago* ITs takes at least 4h (Gage, 2002), these findings imply that exocytosis of  
4 extracellular material towards the newly formed infection chamber initiates before significant  
5 rhizobial multiplication has occurred within the chamber.

### 7 ***The Mtnin-1 mutant is impaired for exocytosis targeted to the infection chamber***

8 We next investigated whether exocytosis targeted to the infection chamber occurred in the  
9 case of the infection mutant *Mtnin-1*, which is able to enclose rhizobia by RH curling but fails  
10 to form ITs and shows impaired multiplication of the enclosed rhizobia (Marsh et al., 2007;  
11 Murray, 2011). Indeed, compared to wild type plants where large rhizobial microcolonies  
12 were present within curled RHs (Fig. 3A), few bacteria were detectable within curled RHs in  
13 the *Mtnin-1* mutant (Fig. 3B-C and Fig. 3D-F). Monitoring GFP-VAMP721e fusion exocytosis-  
14 related localization in *nin* RH curls revealed that in this case the entrapment of rhizobia in  
15 curled RHs was never followed by GFP-VAMP721e accumulation around the infection  
16 chamber (Fig. 3D-F and Suppl. Fig. S2), despite the fact that the localization of the fusion  
17 protein at the tip of growing RHs was otherwise similar to that in wild type (Suppl. Fig. S3).  
18 Furthermore, the nucleus and associated cytoplasm moved down the RH shaft after a few  
19 hours in the *nin* mutant (Fig. 3 D-F) whereas they remain close to the enclosed bacteria in  
20 wild type plants (Fig. 1 A-D, Fig. 2A-C). The absence of exocytotic activity is consistent with  
21 the lack of radial expansion of the infection chamber in curled *nin* RHs (Fig. 3G-I and Suppl.  
22 Fig. S2). Taken together, this indicates that MtNIN is required to initiate the remodeling of the  
23 infection chamber following rhizobial entrapment.

### 25 ***The extracellular MtENOD11 protein is targeted to the infection chamber following*** 26 ***rhizobial entrapment***

27 To examine whether exocytotic activity in the infection chamber is associated with cell wall  
28 remodeling, we monitored the accumulation of the rhizobial infection-associated extracellular  
29 protein MtENOD11. Recently we have found that a YFP-tagged MtENOD11 fusion protein,  
30 when expressed under the control of native promoter sequences (Boisson-Dernier et al.,  
31 2005), accumulates at the periphery of elongating ITs in *M. truncatula* RHs, and especially at  
32 the growing IT tips (Fournier, Teillet, Auriac, Barker, de Carvalho-Niebel, manuscript in  
33 preparation). Using the same YFP-tagged protein fusion, an intense fluorescent signal could  
34 be observed within the center of the curled hair before IT formation (Fig. 4A-B). This  
35 focalized accumulation around the entrapped bacteria is similarly observed in the less

frequent situation where the symbiotic bacteria have become entrapped between the walls of two growing RHs (Fig. 4C-D). Once the tubular IT has initiated from the infection chamber, the fluorescent protein is also found associated to the growing IT tip as expected (Fig. 4C). The intense YFP-MtENOD11 fluorescence is specific to the cell wall matrix associated with rhizobial infection structures including the infection chamber, contrasting with the very low levels of YFP fluorescence labeling the RH walls (Fig. 4A-B and Fournier, Teillet, Auriac, Barker, de Carvalho-Niebel, manuscript in preparation). This implies that the cell wall matrix surrounding rhizobia has a particular composition that is distinct from the normal RH extracellular matrix. In line with this, this region also differs with respect to cell wall auto-fluorescence. RH walls display intrinsic fluorescence that can be used to visualize the cell contours (e.g. Fig. 1A-E, right panels and Fig. 4B). Under identical conditions, the wall matrix directly surrounding the enclosed rhizobia and corresponding to the region of maximal YFP-MtENOD11 accumulation (Fig. 4A) is totally devoid of auto-fluorescent material (Fig. 1A-E and Fig. 4B). Intriguingly, a strong auto-fluorescent signal can be observed in a limited region of the wall adjacent to the infection chamber (Fig. 1C-E and Fig. 4B). Additional studies will be needed to identify the chemical nature of this autofluorescent material, whose accumulation is independent of exocytosis processes related to MtVAMP721e, and whether it results from local increased secretion of phenolics or other compounds, or from enzymatic modifications to existing cell wall components. In conclusion, these observations indicate that during the lengthy period between RH curling and IT initiation, the wall/matrix surrounding the rhizobia within the expanding infection chamber is characterized by the absence of auto-fluorescent material and a strong and focused accumulation of the MtENOD11 Pro-rich protein, supporting the idea that specific wall remodeling is taking place in the chamber during this period.

## Discussion

During the establishment of the RNS in many legumes such as *M. truncatula* root entry by rhizobia occurs *via* a process which initiates with the physical entrapment of the bacteria between RH cell walls followed by the formation of the tip-growing apoplastic ITs. In order to initiate studies on the molecular/cellular processes which accompany the transition between rhizobial entrapment and IT formation we performed time-lapse confocal imaging on *M. truncatula* roots undergoing rhizobial colonization. These experiments unexpectedly revealed that there is a lengthy delay (from 10-20 h) before tubular IT formation is initiated from within fully curled RHs (Fig. 1). Although rarely examined in earlier studies of rhizobial infection, this finding is consistent with light microscopy experiments performed over 30 years ago on inoculated clover roots (Callaham and Torrey, 1981). Most importantly, our live-tissue

1 imaging studies provide strong evidence that major, *NIN*-dependent host cell wall re-  
2 modeling occurs within the infection chamber throughout the entire period preceding IT  
3 initiation, and this discovery leads us to propose a new two-stage model to explain the  
4 cellular mechanisms underlying this critical phase of rhizobial RH infection.

#### 5 *Remodeling of the infection chamber into a novel infection thread-like compartment*

6 The localization of fluorescent markers labeling both the exocytosis reporter MtVAMP721e  
7 and the infection-associated secreted protein MtENOD11 have shown that the RH cell  
8 actively remodels the infection chamber during the 10-20 h period preceding IT formation  
9 (Fig. 2 and Fig. 4). Indeed, this sustained exocytotic activity and concomitant deposition of  
10 extracellular material visualized with the MtENOD11 fusion protein correlates with  
11 progressive enlargement of the infection chamber (Fig.2 and Suppl. Fig. S1), a stage that  
12 has been described as the development of the 'refractile spot' or 'cell wall swelling' in early  
13 studies (Fåhræus, 1957).

14 Although the early accumulation of MtENOD11 throughout the period of infection chamber  
15 remodeling is consistent with the early transcriptional activation of the gene in curled RHs  
16 before IT formation (Boisson-Dernier et al., 2005), the focalized accumulation of the  
17 MtENOD11 protein exclusively around the entrapped bacteria is an intriguing observation.  
18 The Pro-rich MtENOD11 is an atypical cell wall-associated protein with unusually low Tyr  
19 content, presumed to limit cross-linking to other wall components (Journet et al., 2001). As  
20 such, the accumulation of MtENOD11 within the chamber is likely to contribute to the cell  
21 wall plasticity required for the radial expansion and the subsequent polar initiation of ITs. The  
22 occurrence of MtENOD11 within the infection chamber therefore leads us to propose a  
23 scenario in which the chamber progressively acquires an IT-like composition prior to tip-  
24 growth initiation (Fig. 5 and Suppl. Movie1). In this scenario, the transport of exocytotic  
25 vesicles towards the membrane surrounding the infection chamber initiates within hours  
26 following the completion of RH curling (Fig. 5A-D). Progressive deposition of new membrane  
27 and extracellular materials including MtENOD11 over the following 10-20 h leads to radial  
28 infection chamber enlargement and conversion into a globular IT-like compartment (Fig. 5E  
29 and Suppl. Movie1). This is accompanied by a small number of rhizobial cell divisions (see  
30 below). At the end of this first phase a switch from radial expansion to polar tip elongation  
31 leads to the initiation of IT development (Fig. 5F and Suppl. Movie1). In this two-step model,  
32 the *Mtnin-1* mutant fails to initiate the first stage of infection chamber remodeling  
33 (corresponding to the transition between stages C and D shown in Fig. 5). In conclusion, we  
34 therefore propose that IT initiation should be viewed as a tip-growing extension emanating  
35 from the IT-like compartment already created within the infection chamber. One important  
36 consequence of this model is that there is no longer any need to hypothesize that localized

1 host cell wall degradation is required for colonizing rhizobia to access the newly formed IT in  
2 contrast to what was previously proposed (Callaham and Torrey, 1981; Turgeon and Bauer,  
3 1985; Gage, 2004). Finally, it should be underlined that our findings also clearly argue  
4 against an additional suggestion that the initiation of IT development might result from a  
5 direct conversion of apical RH tip-growth to inward-directed IT tip-growth (e.g. Brewin, 1991;  
6 Kijne, 1992).

#### 7 *Plant-microsymbiont signal exchange during the two stages of rhizobial entry*

8 In the light of this new two-step model for rhizobial infection, what do we know about the  
9 various factors that are involved in infection chamber remodeling and the initiation of tubular  
10 IT growth? Recent data has revealed that *Rhizobium*-elicited  $\text{Ca}^{2+}$  spiking in the RH is  
11 strongly attenuated in fully curled hairs with entrapped rhizobia, and that sustained spiking is  
12 re-activated prior to and during the entry of the bacteria into the newly created IT (Sieberer et  
13 al., 2015). This suggests that there are sequential modifications in the host perception of  
14 rhizobial LCO signals during these key stages, and that the capacity to perceive these  
15 signals may be important in the triggering of IT initiation. Indeed, this is in line with the  
16 proposal that IT development within the *M. truncatula* RH requires that the host perceives  
17 NF-related signals *via* a specific “entry” receptor involving the LysM receptor-like kinase  
18 LYK3 (Limpens et al., 2003; Smit et al., 2007). Further evidence for distinct sequential steps  
19 prior to IT formation comes from the *S. meliloti nodFnodL* mutant which produces abnormal  
20 NFs and cannot activate IT formation, despite the fact that rhizobial entrapment and  
21 multiplication take place (Ardourel et al., 1994) in addition to the trigger of infection-related  
22 *MtENOD11* expression (Boisson-Dernier et al., 2005). Confocal imaging experiments have  
23 revealed that a single attached bacterium is often sufficient to induce initial RH tip curling  
24 (Fig. 1, Fig. 2G, H) and that a small rhizobial micro-colony comprising from 10-30 bacteria is  
25 present within the infection chamber by the time the IT is initiated (Fig. 2 D-F). It is  
26 conceivable that rhizobial multiplication within the chamber may be an important parameter  
27 in generating threshold levels of bacterial signal molecules required for triggering IT initiation.  
28 Furthermore, the modified environment generated within the chamber by focused exocytosis  
29 may play a role in activating rhizobial differentiation and associated responses necessary for  
30 successful infection including the secretion of infection-related LCOs and other important  
31 components such as acidic exopolysaccharides (reviewed in Downie, 2010).

32 The *nin* mutants in *Lotus*, pea or *M. truncatula* (Schauser et al., 1999; Borisov et al., 2003;  
33 Marsh et al., 2007) are able to respond to rhizobial inoculation by RH curling leading to  
34 rhizobial entrapment (a stage depicted in Fig. 5C) but do not progress to tubular IT initiation.  
35 We now show that this is most likely the result of the failure of infection chamber remodeling  
36 and associated microcolony development. In *Lotus*, the recently characterized pectate lyase

1 NPL (Xie et al., 2012) that is required for proper infection is regulated by NIN. It is therefore  
2 possible that the infection-defective phenotype of *Mtnin-1* results at least in part from the lack  
3 of expression of an orthologous *M. truncatula* pectate lyase. Identifying and characterizing  
4 NIN targets in *Medicago* will be important to understand the infection chamber remodeling  
5 process. The two-step model for infection is also consistent with the phenotypes of other  
6 legume mutants defective for rhizobial infection. For example, *Ljycyclops* (Yano et al., 2008)  
7 or *Mtlin* (Kuppusamy et al., 2004; Guan et al., 2013) mutants appear to be impaired at the  
8 intermediate stage (depicted in Fig. 5E) following rhizobial microcolony development but  
9 preceding tubular IT initiation. It will now be important to identify and study additional host  
10 and bacterial cell wall-associated components involved in the development of the rhizobial  
11 infection chamber compartment including cell wall modifying enzymes proposed to be  
12 required for IT formation such as *Lotus* NPL (Xie et al., 2012) or the *Rhizobium* cell-bound  
13 cellulase CelC2 (Robledo et al., 2008).

#### 14 15 *Is infection chamber remodeling a specificity of the Rhizobium-legume symbiosis?*

16 As underlined in the introduction, there are a number of striking similarities between the early  
17 infection stages of the rhizobial and AM associations, both in terms of host/microbe signaling  
18 pathways and the mechanisms involved in the respective host-regulated apoplastic infection  
19 processes (Parniske, 2008; Bapaume and Reinhardt, 2012). AM fungi also penetrate plant  
20 roots via a host-constructed transcellular compartment equivalent to the rhizobial IT. The  
21 development of this specialized peri-fungal compartment is prefigured by the formation of the  
22 transient cytoplasmic PPA, which links the migrating cell nucleus to the site of AM fungal  
23 attachment via the hyphopodium (Genre et al., 2005; Genre et al., 2008). In addition, Rich *et*  
24 *al.* (2014) have recently proposed that host cell-driven modifications to the cell wall at the site  
25 of hyphopodium contact would precede *Rhizophagus irregularis* entry into the *Petunia hybrid*  
26 root. Thus, by analogy with the creation of the IT precursor within the enclosed space formed  
27 by RH curling, it is possible that hyphopodium attachment also creates an enclosed  
28 environment within which host secretion and associated wall remodeling generates a  
29 specialized compartment, thus allowing the AM hyphae to cross the host cell wall. Future  
30 studies focused on this key step preceding AM fungal cell penetration will now be needed to  
31 address this intriguing question.

## Materials and Methods

### Biological materials

The *M. truncatula sunn-2* mutant was used for most of the experiments described in this article because its enhanced infection phenotype (Schnabel et al., 2005) greatly facilitates the identification of RH infection sites, whilst at the same time possessing a normal wild type infection process (Fournier et al., 2008; Cerri et al., 2012; Sieberer et al., 2012). The *M. truncatula nin-1* mutant, kindly provided by Giles Oldroyd and Tatiana Vernié, and *M. truncatula* cv Jemalong A17 were also used in this study, and all plants were grown as described previously (Fournier et al., 2008). Strains of *Sinorhizobium meliloti* 2011 constitutively expressing either GFP (*Sm* 2011-GFP) or the Cerulean version of CFP (*Sm* 2011-cCFP) (both kindly provided by P. Smit, University of Wageningen, The Netherlands) or a *hemA-lacZ* fusion (*Sm* 2011-*lacZ*; Ardourel et al., 1994) were propagated as described (Cerri et al., 2012).

### Expression of fluorescent protein fusions in *M. truncatula* roots

The GFP-MtVAMP721e fusion (Ivanov et al., 2012) was expressed under the control of the *A. thaliana* *UBQ3* promoter in a pK7WGF2-R-derived binary vector carrying the 'Red Root' selection marker which comprises the DsRed coding sequence driven by the *A. thaliana* *UBQ10* promoter (Smit et al., 2005; Limpens et al., 2009). The construction of the chimeric gene expressing YFP-labelled MtENOD11 is described in detail in (Fournier, Teillet, Auriac, Barker, de Carvalho-Niebel, in preparation). In this construct YFP has been inserted between the N-terminal ENOD11 signal peptide (75 bp) and the remaining repetitive Pro-rich domain (450 bp), and expression is driven by a 1 kb fragment of the endogenous ENOD11 promoter (pE11) that is sufficient for both pre-infection and infection-related expression (Boisson-Dernier et al., 2005). The pUBQ3-GFP-MtVAMP721e and pE11-YFP-MtENOD11 constructs were introduced into *Agrobacterium rhizogenes* ARqual (Quandt et al., 1993) and composite *sunn-2* or *nin-1* plants were produced via *A. rhizogenes*-mediated transformation as described in (Boisson-Dernier et al., 2001). Composite plants with roots constitutively expressing the GFP-MtVAMP721e fusion were selected under the stereomicroscope for moderate and uniform fluorescence levels. Those with roots expressing pE11-YFP-MtENOD11 were selected on Fåhræus medium supplemented with 25 µg.ml<sup>-1</sup> kanamycin.

### In vivo microscopy of rhizobial infection sites in root hairs

Rhizobial inoculation for *in vivo* microscopic observation was performed essentially as described (Fournier et al., 2008; Sieberer et al., 2012). Briefly, plants were placed in 12x12cm Petri dishes containing a modified Fåhræus medium (Phytigel 0.5%) supplemented with 50nM 2-amino ethoxyvinyl glycine (AVG). Roots were covered with a

gas-permeable plastic film (Lumox Film, Starsted, France), and plants grown with the dishes slightly tilted to encourage the growth of the roots along the plastic film. Inoculation with *Sm* 2011-GFP or *Sm* 2011-cCFP strains was performed by introducing 0.5-1 mL of an aqueous suspension of exponentially growing bacteria ( $OD_{600} = 0.001$ ; approx.  $10^6$  bacteria.mL<sup>-1</sup>) under the plastic film. To investigate the early stages of rhizobial infection, roots of inoculated plants were observed 1 to 4 d post-inoculation. Curled RHs with enclosed fluorescent bacteria as well as bacterial entrapment between cell walls of adjacent RHs were identified as potential sites for imaging. In addition, preference was given to curled RHs where the nucleus was located close to the enclosed rhizobia and associated with significant quantities of cytoplasm since experience had shown that these were more likely to initiate ITs. Plants were returned to the culture room between observations. Data were obtained from a total of 18 experiments in *sun-2* and 2 experiments in *Jemalong A17* and *Mtnin-1*. The results presented are representative of observations recorded on 27 (Fig. 1), 24 (Fig. 2), 10 (Fig. 3D-I) and 15 (Fig. 4) rhizobial infection sites, monitored using 20, 15, 2 and 12 independent plants, respectively. The duration of the interval between curl closure and IT initiation was evaluated for 7 sites (5 independent experiments) and corroborated by data from an additional 20 sites monitored over longer intervals.

### **Confocal microscopy**

Selected infection sites were imaged with a Leica TCS SP2 AOBS confocal laser scanning microscope equipped with a long-distance 40x HCX Apo L NA 0.80 water-immersion objective. The argon laser bands of 458nm, 488nm and 514nm were used to excite CFP, GFP and YFP, respectively, and a 561-nm diode to excite the DsRed and observe cell wall autofluorescence. Specific emission windows used for CFP, GFP, YFP, DsRed and autofluorescence signals were 465 to 485 nm, 500 to 530 nm, 525 to 550nm, 600 to 630 and 620 to 720 nm respectively, and emitted fluorescence was false-colored in magenta (CFP), green (GFP or YFP) and red (DsRed and/or wall autofluorescence). The images shown are single confocal sections, maximal projections of selected planes of a z-stack or 3D-reconstructions of confocal image stacks. Images were acquired and projected using Leica confocal software and processed using Leica, ImageJ (<http://imagej.nih.gov/ij/>) or Volocity version 6.0.1 (Perkin-Elmer) softwares.

### ***β*-galactosidase assay**

Histochemical staining for *β*-galactosidase activity after inoculation with *S. meliloti* strain *Sm* 2011-*lacZ* was performed 3 d post inoculation using X-gal as substrate (Boivin et al., 1990). Data in Fig. 3A-C are representative of results obtained in 10 A17 and 10 *Mtnin-1* plants.

## **Supplemental Material**

**Supplemental Figure S1.** Radial expansion of the infection chamber prior to thread initiation.

**Supplemental Figure S2.** Infection chamber development and associated rhizobial multiplication are blocked in curled root hairs of the *Mtnin* mutant.

**Supplemental Figure S3.** Before infection chamber closure, the localization of GFP-VAMP721e in *Mtnin-1* root hairs is similar to that in a wild-type plant.

**Supplemental Movie 1.** Animation illustrating the 2-step model for rhizobial root hair infection initiation.

## **Acknowledgements**

We are grateful to P. Smit (Wageningen, The Netherlands) for providing the *S. meliloti* 2011 strains expressing cCFP or GFP, to Tatiana Vernié and Giles Oldroyd (John Innes Center, UK) for providing the *Mtnin-1* seeds and to Alain Jauneau and colleagues from the FR 3450 imagery facility for their assistance with confocal microscopy.

## Figure legends

**Figure 1.** Infection thread initiation does not immediately follow rhizobial entrapment within the curled root hair. Bright field (left panel) and the corresponding confocal (right panel) images of a *M. truncatula* RH at different times following tip curling around GFP-labelled *S. meliloti* 2011. In the bright field images the location of the nucleus (n) is indicated, as well as the position of the RH tip (arrowhead, A-C). In the fluorescence images the region of the cell wall adjacent to the infection chamber where auto-fluorescent material accumulates is indicated (double arrowhead, C-E). Note that the IT walls (E) are devoid of auto-fluorescent material in contrast to the rest of the RH wall. Confocal images of GFP fluorescence (single optical sections across the infection chamber) were superposed either with the laser transmission images (left panel) or with the cell wall auto-fluorescence (right panel). cb: cytoplasmic bridge. Bars = 10  $\mu$ m.

**Figure 2.** GFP-MtVAMP721e identifies exocytotic activity surrounding the infection chamber in curled root hairs. A to C, The intracellular localization of the GFP-MtVAMP721e fusion (green) in *M. truncatula* RHs was imaged over a 7 h period in both a curled hair and an adjacent tip-growing hair after inoculation with cCFP-labeled *S. meliloti* (magenta). A, The GFP-VAMP721e fusion protein fluorescence surrounds the enclosed bacteria (open arrowhead) within the infection chamber of the curled RH (left hair, arrow) whereas GFP fluorescence localizes predominantly to the tip of the growing RH (hair on the right, solid arrowhead). B and C, Throughout the 7 h monitoring period the GFP fluorescence localizes to the periphery of the infection chamber, which undergoes progressive radial expansion within the curled RH. D to F, Identical RH as in A-C, showing in more detail that the cCFP-labeled rhizobia within the infection chamber (open arrowhead) have multiplied concomitantly with chamber expansion. The dashed lines indicate the RH contours. G to J, GFP-MtVAMP721e localization in RHs that are just completing curling. The completion of RH curling around an attached Rhizobium (open arrowhead) occurs during the 1h30 observation period, and is associated with the rapid loss (dashed arrow in H) of the tip-localized GFP fluorescence (arrow in G). I and J, In a second RH, two different stages are identified by GFP-MtVAMP721e localization (arrows). I, As in (G), tip-localized GFP fluorescence indicates that the RH is still curling. J, 3h30 later, curling has terminated and GFP is now found predominantly around the closed infection chamber (open arrowhead), whereas the RH tip fluorescence has been lost (not in focal plane). Confocal images are based on single optical sections across the infection chamber for A-C, z-axis projections of 7 serial optical sections encompassing the entire rhizobial microcolony for D-F, three-dimensional images reconstructed from confocal z-stacks (22 serial optical sections) for G-H, z-axis projection of 5 serial optical sections encompassing the RH tip and attached rhizobia for I and z-axis

projection of 2 serial optical sections across the infection chamber for J. n: nucleus. Bars = 10  $\mu$ m.

**Figure 3.** In the infection-defective *Mtnin* mutant entrapment of rhizobia within the infection chamber is not followed by targeted exocytosis nor bacterial multiplication. A to C, Rhizobial microcolony development is strongly reduced in *Mtnin-1* compared to the wild type (WT), as indicated by the level of  $\beta$ -galactosidase activity of *S. meliloti* (*hemA-LacZ*) colonies (arrows) entrapped within curled RHs of wild type A17 (A) or *Mtnin-1* (B, C) plants. D to F, The GFP-VAMP721e fusion protein does not accumulate at the periphery of the infection chamber (arrowhead) in *Mtnin-1* plants expressing the exocytosis reporter, although cCFP-labeled *S. meliloti* (magenta) are present in the chamber. Note that, as for the wild type, background GFP-VAMP721e fluorescence was detected in both the cytoplasm and cytoplasmic bodies. G to I, Consistent with A-C, the rhizobial microcolony in the *nin* mutant does not visibly enlarge over the observation period compared to wild type (see Fig. 2). The dashed lines indicate the RH contours. n, nucleus. Bars = 10  $\mu$ m.

**Figure 4.** YFP-MtENOD11 accumulates within the rhizobial infection chamber preceding infection thread initiation. Early RH infection sites were imaged in *M. truncatula* roots expressing a YFP-tagged ENOD11 fusion (green) following inoculation with cCFP-expressing *S. meliloti* (magenta). A and B, Prior to IT formation, the YFP-MtENOD11 fluorescence (arrow, A) is mainly associated with the infection chamber surrounding the enclosed rhizobia (open arrowhead, A-B). The double arrowhead indicates the auto-fluorescent wall domain (in red) adjacent to the infection chamber contrasting with the absence of autofluorescence associated to the infection chamber (dashed arrow in B). C and D, An IT is initiating from an infection chamber that has formed after rhizobia have become entrapped between two touching RHs (RH1 and RH2). YFP-MtENOD11 accumulation is associated with the site of initial rhizobial enclosure between touching walls (arrow), the protruding infection chamber formed in RH2 (open arrowhead), as well as the tip of the initiating IT (bracket). Confocal images are z-axis projections of 5 (A-B) or 13 (C,D) serial optical sections. A, C: overlays of cCFP (magenta), YFP (green) and auto-fluorescence (red); and B, D: overlays of cCFP and auto-fluorescence. The dashed lines in D indicate the contours of the RH cells. Bars = 10  $\mu$ m.

**Figure 5.** Infection chamber remodeling paves the way for polar infection thread initiation in *M. truncatula* root hairs. The localization of the exocytosis reporter and the MtENOD11 protein during RH curling, infection chamber remodeling and IT initiation are schematically represented. A to C, During RH curling, the GFP-VAMP721e-labeled exocytosis site at the growing RH tip (A-B) is lost once RH curling is completed (C). At this stage, the infection chamber generally encloses a single *Rhizobium* cell. D to F, Remodeling of the infection chamber starts during the following hours before significant rhizobial multiplication has

occurred (D) and leads to enlargement and differentiation of this new compartment accompanied by rhizobial multiplication (E) prior to tubular IT initiation (F). Note that the *Mtnin-1* mutant fails to progress from stage C to stage D. Color code: Rhizobia, pink; GFP-MtVAMP721e, green; YFP-MtENOD11, yellow.

**Supplemental Figure S1.** Radial expansion of the infection chamber prior to thread initiation. During the lengthy 10-20 h period preceding IT initiation, the infection chamber (arrow) progressively enlarges and becomes clearly distinguishable from the surrounding cytoplasm. This is likely to be the result of exocytotic activity and wall remodeling. The RH tip is the same as that shown in Fig. 1. n, nucleus. Bar = 10  $\mu$ m.

**Supplemental Figure S2.** Infection chamber development and associated rhizobial multiplication are blocked in curled root hairs of the *Mtnin* mutant. Images of the identical RH extremity shown in Fig. 3 (D to I) taken at later time-points as indicated show that neither infection chamber labeling with GFP-VAMP721e nor multiplication of the enclosed cCFP-labeled rhizobia (arrowhead) have significantly changed, indicating that both processes are blocked rather than simply delayed in the *Mtnin-1* mutant. The dashed lines indicate the RH contours. Bar = 10  $\mu$ m.

**Supplemental Figure S3.** Before infection chamber closure, the localization of GFP-VAMP721e in *Mtnin-1* root hairs is similar to that in a wild-type plant. In *Mtnin-1* roots expressing the GFP-MtVAMP721e fusion (green), the main GFP fluorescence in a growing, non-curved root hair (A-B) or a curling root hair (C,D) is associated to the vesicle-rich region at the growing tip (solid arrowhead) similar to wild-type growing root hairs (see Figure 2A) and wild-type curling root hairs (see Fig.2G and I). Bar = 10  $\mu$ m.

**Supplemental Movie 1.** Animation illustrating the 2-step model for rhizobial root hair infection initiation. The first 15 s of the animation illustrate the processes of RH tip growth, *Rhizobium* attachment and resulting re-orientation of RH tip growth till rhizobial entrapment. The second half of the animation represents a virtual section across the curled RH and is broadly based on the scheme shown in Figure 5D-F with the exocytosis activity represented by the accumulation of vesicles (dark blue) initially at the periphery of the radially growing infection chamber and then subsequently at the apically growing tip of the IT. Note also that, according to results presented in an earlier publication (Fournier et al., 2008), IT tip growth always precedes rhizobial colonization and that this progressive colonization of the IT occurs both by division and physical movement (sliding) of the bacteria. Other color coding:

- 1 Rhizobia, red; Plant cytoplasm, light blue; Nucleus, green; Infection chamber/IT lumen,
- 2 yellow; Vacuole, grey.
- 3

**Figure 1.** Infection thread initiation does not immediately follow rhizobial entrapment within the curled root hair. Bright field (left panel) and the corresponding confocal (right panel) images of a *M. truncatula* RH at different times following tip curling around GFP-labelled *S. meliloti* 2011. In the bright field images the location of the nucleus (n) is indicated, as well as the position of the RH tip (arrowhead, A-C). In the fluorescence images the region of the cell wall adjacent to the infection chamber where auto-fluorescent material accumulates is indicated (double arrowhead, C-E). Note that the IT walls (E) are devoid of auto-fluorescent material in contrast to the rest of the RH wall. Confocal images of GFP fluorescence (single optical sections across the infection chamber) were superposed either with the laser transmission images (left panel) or with the cell wall auto-fluorescence (right panel). cb: cytoplasmic bridge. Bars = 10  $\mu$ m.

**Figure 2.** GFP-MtVAMP721e identifies exocytotic activity surrounding the infection chamber in curled root hairs. A to C, The intracellular localization of the GFP-MtVAMP721e fusion (green) in *M. truncatula* RHs was imaged over a 7 h period in both a curled hair and an adjacent tip-growing hair after inoculation with cCFP-labeled *S. meliloti* (magenta). A, The GFP-VAMP721e fusion protein fluorescence surrounds the enclosed bacteria (open arrowhead) within the infection chamber of the curled RH (left hair, arrow) whereas GFP fluorescence localizes predominantly to the tip of the growing RH (hair on the right, solid arrowhead). B and C, Throughout the 7 h monitoring period the GFP fluorescence localizes to the periphery of the infection chamber, which undergoes progressive radial expansion within the curled RH. D to F, Identical RH as in A-C, showing in more detail that the cCFP-labeled rhizobia within the infection chamber (open arrowhead) have multiplied concomitantly with chamber expansion. The dashed lines indicate the RH contours. G to J, GFP-MtVAMP721e localization in RHs that are just completing curling. G and H, The completion of RH curling around an attached Rhizobium (open arrowhead) occurs during the 1h30 observation period, and is associated with the rapid loss (dashed arrow in H) of the tip-localized GFP fluorescence (arrow in G). I and J, In a second RH, two different stages are identified by GFP-MtVAMP721e localization (arrows). I, As in (G), tip-localized GFP fluorescence indicates that the RH is still curling. J, 3h30 later, curling has terminated and GFP is now found predominantly around the closed infection chamber (open arrowhead), whereas the RH tip fluorescence has been lost (not in focal plane). Confocal images are based on single optical sections across the infection chamber for A-C, z-axis projections of 7 serial optical sections encompassing the entire rhizobial microcolony for D-F, three-dimensional images reconstructed from confocal z-stacks (22 serial optical sections) for G-H, z-axis projection of 5 serial optical sections encompassing the RH tip and attached rhizobia for I and z-axis projection of 2 serial optical sections across the infection chamber for J. Scale Bars = 10  $\mu$ m.

**Figure 3.** In the infection-defective *Mtnin* mutant entrapment of rhizobia within the infection chamber is not followed by targeted exocytosis nor bacterial multiplication. A to C, Rhizobial microcolony development is strongly reduced in *Mtnin-1* compared to the wild type (WT), as indicated by the level of  $\beta$ -galactosidase activity of *S. meliloti* (*hemA-LacZ*) colonies (arrows) entrapped within curled RHs of wild type A17 (A) or *Mtnin-1* (B, C) plants. D to F, The GFP-VAMP721e fusion protein does not accumulate at the periphery of the infection chamber (arrowhead) in *Mtnin-1* plants expressing the exocytosis reporter, although cCFP-labeled *S. meliloti* (magenta) are present in the chamber. Note that, as for the wild type, background GFP-VAMP721e fluorescence was detected in both the cytoplasm and cytoplasmic bodies. G to I, Consistent with A-C, the rhizobial microcolony in the *nin* mutant does not visibly enlarge over the observation period compared to wild type (see Fig. 2). The dashed lines indicate the RH contours. n, nucleus. Bars = 10  $\mu$ m.

**Figure 4.** YFP-MtENOD11 accumulates within the rhizobial infection chamber preceding infection thread initiation. Early RH infection sites were imaged in *M. truncatula* roots expressing a YFP-tagged ENOD11 fusion (green) following inoculation with cCFP-expressing *S. meliloti* (magenta). A and B, Prior to IT formation, the YFP-MtENOD11 fluorescence (arrow, A) is mainly associated with the infection chamber surrounding the enclosed rhizobia (open arrowhead, A-B). The double arrowhead indicates the auto-fluorescent wall domain (in red) adjacent to the infection chamber contrasting with the absence of autofluorescence associated to the infection chamber (dashed arrow in B). C and D, An IT is initiating from an infection chamber that has formed after rhizobia have become entrapped between two touching RHs (RH1 and RH2). YFP-MtENOD11 accumulation is associated with the site of initial rhizobial enclosure between touching walls (arrow), the protruding infection chamber formed in RH2 (open arrowhead), as well as the tip of the initiating IT (bracket). Confocal images are z-axis projections of 5 (A-B) or 13 (C,D) serial optical sections. A, C: overlays of cCFP (magenta), YFP (green) and auto-fluorescence (red); and B, D: overlays of cCFP and auto-fluorescence. The dashed lines in D indicate the contours of the RH cells. Bars = 10 μm.

**Figure 5.** Infection chamber remodeling paves the way for polar infection thread initiation in *M. truncatula* root hairs. The localization of the exocytosis reporter and the MtENOD11 protein during RH curling, infection chamber remodeling and IT initiation are schematically represented. A to C, During RH curling, the GFP-VAMP721e-labeled exocytosis site at the growing RH tip (A-B) is lost once RH curling is completed (C). At this stage, the infection chamber generally encloses a single *Rhizobium* cell. D to F, Remodeling of the infection chamber starts during the following hours before significant rhizobial multiplication has occurred (D) and leads to enlargement and differentiation of this new compartment accompanied by rhizobial multiplication (E) prior to tubular IT initiation (F). Note that the *Mtnin-1* mutant fails to progress from stage C to stage D. Color code: Rhizobia, pink; GFP-MtVAMP721e, green; YFP-MtENOD11, yellow.
